ABSTRACT

We obtain stringent constraints on the actual efficiency of mass loss for red giant branch stars in the Galactic globular cluster 47 Tuc, by comparing synthetic modeling based on stellar evolution tracks with the observed distribution of stars along the horizontal branch in the colour-magnitude-diagram. We confirm that the observed, wedge-shaped distribution of the horizontal branch can be reproduced only by accounting for a range of initial He abundances – in agreement with inferences from the analysis of the main sequence – and a red giant branch mass loss with a small dispersion. We have carefully investigated several possible sources of uncertainty that could affect the results of the horizontal branch modeling, stemming from uncertainties in both stellar model computations and the cluster properties such as heavy element abundances, reddening and age. We determine a firm lower limit of $\sim 0.17M_{\odot}$ for the mass lost by red giant branch stars, corresponding to horizontal branch stellar masses between $\sim 0.65M_{\odot}$ and $\sim 0.73M_{\odot}$ (the range driven by the range of initial helium abundances). We also derive that in this cluster the amount of mass lost along the asymptotic giant branch stars is comparable to the mass lost during the previous red giant branch phase. These results confirm for this cluster the disagreement between colour-magnitude-diagram analyses and inferences from recent studies of the dynamics of the cluster stars, that predict a much less efficient red giant branch mass loss. A comparison between the results from these two techniques applied to other clusters is required, to gain more insights about the origin of this disagreement.

Key words. globular clusters: individual: 47 Tucanae – stars: evolution – stars: horizontal-branch – stars: low-mass – stars: mass-loss

1. Introduction

Mass loss during the red giant branch (RGB) evolution of globular cluster (GC) stars has a generally negligible effect on their structure (unless the RGB star is experiencing very high mass loss rates, see Castellani & Castellani 1993), but it is crucial to interpret the colour-magnitude-diagram (CMD) of the following horizontal branch (HB) phase, and affects the CMD and duration of the asymptotic giant branch (AGB) stage.

A comprehensive physical description of RGB mass loss processes is still lacking, and RGB mass loss rates are customarily parametrized in stellar evolution calculations by means of simple relations like the Reimers formula (Reimers 1975), or more recently the Schröder & Cuntz (2005) one. These prescriptions are essentially scaling relations between mass loss rates and global stellar parameters like surface bolometric luminosity (L) and gravity (g), effective temperature (T_{eff}) and/or radius (R). The zero point of these scaling relations is typically set by a free parameter (η) that needs to be calibrated.

The more direct approach to study the mass loss in RGB stars is to detect outflow motions in the outer regions of the atmospheres (for example the presence of asymmetries and coreshifts in chromospheric lines, see, e.g., Mauas et al. 2006; Vieytes et al. 2011), or detect the circumstellar envelopes at larger distances from the stars (for example through infrared dust emission, see, e.g., Origlia et al. 2007, 2010; Boyer et al. 2010; Momany et al. 2012). Another traditional indicator of the efficiency of RGB mass loss is the CMD location and morphol-

ogy of the HB of globular clusters, starting from the pioneering works by Iben & Rood (1970) and Rood (1973). Matching observed HBs with synthetic HB models traditionally requires that RGB stars lose a fraction of their initial mass, with typical values of the order of $\sim 0.2 M_{\odot}$ (see, e.g., Lee et al. 1990; Catelan 1993; Salaris et al. 2007; di Criscienzo et al. 2010; Gratton et al. 2010; Dalessandro et al. 2013; McDonald & Zijlstra 2015, and references therein).

A very recent series of papers (Heyl et al. 2015b,a) has applied a completely different approach to estimate the mass lost by RGB stars in the Galactic GC 47 Tuc. Using *HST* images these authors determined the rate of diffusion of stars through the cluster core, using a sample of bright white dwarfs (WDs). They then compared the radial distribution of upper main sequence (MS), RGB and HB stars, showing that they are nearly identical, even when only objects near the RGB tip are considered, whilst the radial distribution of young WDs is only slightly less concentrated than upper MS and RGB stars, indicating that there has been very little time for the young WDs to have diffused through the cluster since their progenitors lost mass. They estimated that most of the $\sim 0.4 M_{\odot}$ that 47 Tuc stars lose between the end of the MS (the typical MS turn-off mass for 47 Tuc as inferred from theoretical isochrones is equal to $\sim 0.9M_{\odot}$) and the beginning of the WD sequence (typical masses for bright WDs in GCs as determined from observations are $\sim 0.53M_{\odot}$, see Kalirai et al. 2009) is shed shortly before the start of the WD cooling. Quantitatively they estimated that mass loss greater than $0.2M_{\odot}$ earlier than 20 Myr before the termination of the AGB

can be excluded with 90% confidence, and that mass loss larger than $0.2M_{\odot}$ during the RGB can be excluded at more than 4σ level. Also, a typical HB stellar mass of the order of $\sim 0.65M_{\odot}$ is excluded by comparisons of the radial distribution of HB stars and $\sim 0.65M_{\odot}$ MS stars.

Regarding more direct estimates of RGB mass loss in 47 Tuc, Origlia et al. (2007) derived that the total mass lost by individual RGB stars is $\Delta M_{\text{RGB}} \sim 0.23 \pm 0.07M_{\odot}$, from the detection of their circumstellar envelopes by means of mid-IR photometry (see also Origlia et al. 2007; Boyer et al. 2010; Momany et al. 2012). This is in contrast with Heyl et al. (2015a) result, but is consistent with published results from synthetic HB modeling, that require RGB stars to have lost typically more than $0.2M_{\odot}$ (Salaris et al. 2007; di Criscienzo et al. 2010; Gratton et al. 2013). On the other hand, observations of the infrared excess around nearby RGB stars (not in GCs) led Groenewegen (2012) to determine a Reimers-like mass loss formula that when used in stellar model calculations predicts negligible mass loss for 47 Tuc RGB stars (Heyl et al. 2015a).

Heyl et al. (2015a) result based on stellar dynamics clearly questions the accuracy of HB stellar models and/or their interpretation of HB morphologies. A solution of this discrepancy requires a robust assessment of the reliability of these two radically different techniques employed to determine the cluster's RGB mass loss. To this purpose we revisit in this paper the theoretical modeling of 47 Tuc HB, discussing various sources of potential uncertainties in synthetic models based on HB evolutionary tracks. Section 2 describes briefly our synthetic modeling and presents our *baseline* synthetic HB for this cluster, with the estimated mean RGB mass loss (ΔM_{RGB}). Section 3 discusses various potential sources of uncertainties in our baseline synthetic HB model, and their impact on the estimated ΔM_{RGB} . A critical discussion and conclusions close the paper.

2. The baseline synthetic HB model for 47 Tuc

We have employed in our analysis the accurate *BVI* cluster photometry by Bergbusch & Stetson (2009), and selected stars between 400 and 900 arcseconds of the cluster centre, to minimize the effect of blending (see the discussion in Bergbusch & Stetson 2009) and field contamination. We present results for the HB modeling in the Johnson $V - (B - V)$ CMD, but we have verified that we reach the same conclusions when using the Johnson-Cousins $V - (V - I)$ CMD instead. We have also compared the $V - (V - I)$ CMD of the cluster central region (transformed from the equivalent *HST* ACS filters to the Johnson-Cousins system by Sarajedini et al. 2007) from the ACS survey of Galactic GCs with our adopted photometry. The HB morphology is the same in the ACS field, with just an offset of about ~ 0.05 mag in the V magnitudes (ACS magnitudes being brighter).

The reddening estimates for 47 Tuc range between $E(B - V) = 0.024$ (Gratton et al. 2003) and $E(B - V) = 0.055$ (Gratton et al. 1997). Schlegel et al. (1998) reddening maps provide $E(B - V) = 0.032$, whilst Harris (1996) catalogue of GC parameters reports $E(B - V) = 0.04$. The amount of differential reddening is negligible, $E(B - V)$ varies around the cluster mean value by at most -0.007 mag and $+0.009$ mag respectively, as recently determined by Marino et al. (2016) on a sample of stars taken from our adopted Bergbusch & Stetson (2009) photometry. As for the cluster chemical composition, Thompson et al. (2010) and Cordero et al. (2014) list a series of spectroscopic determinations of $[\text{Fe}/\text{H}]$ and $[\alpha/\text{Fe}]$ for this cluster that can be summarized as $[\text{Fe}/\text{H}] = -0.7 \pm 0.1$ and $[\alpha/\text{Fe}] = 0.3 -$

0.4 . $[\text{Fe}/\text{H}]$ measurements in a sample of 47 Tuc HB stars provide $[\text{Fe}/\text{H}] = -0.76 \pm 0.01$ (rms = 0.06 dex), consistent with the range quoted above (Gratton et al. 2013).

In our baseline simulation of the cluster HB we have assumed $[\text{Fe}/\text{H}] = -0.70$, $[\alpha/\text{Fe}] = 0.4$ and $E(B - V) = 0.024$. We employed the lowest estimate of the cluster reddening because it leads to generally higher HB masses, hence minimizes the necessary RGB mass loss¹.

Synthetic HB models have been computed by employing HB tracks from the BaSTI stellar model library (Pietrinferni et al. 2004, 2006)², and the code fully described in Dalessandro et al. (2013). We made use of the BaSTI tracks for $[\text{Fe}/\text{H}] = -0.7$, $[\alpha/\text{Fe}] = 0.4$ (corresponding to $Z = 0.008$), and varying Y .

Our calculations require the specification of four parameters, plus the cluster initial composition, age, and the photometric error. Two of these parameters are related to the distribution of the initial He abundances among the cluster stars. We can choose between a Gaussian distribution with a mean value $\langle Y \rangle$ and spread $\sigma(Y)$, and a uniform distribution with minimum value Y_{min} and range ΔY . The other two parameters are the mean value of the mass lost along the RGB, ΔM_{RGB} –that for simplicity we assume to be the same for each Y , but can be made Y -dependent– and the spread around this mean value ($\sigma(\Delta M_{\text{RGB}})$). The idea behind this type of simulations (see, e.g., D'Antona et al. 2002; Gratton et al. 2010; Dalessandro et al. 2013; Milone et al. 2014, and references therein) is that the colour extension of the HB is driven mainly by the variation of Y rather than mass-loss efficiency. A range of He-abundances within individual clusters is expected theoretically given the well-established presence of CN, ONa, MgAl abundance anticorrelations within single GCs (see, i.e., Gratton et al. 2004). These abundance variations are most likely produced by high-temperature CNO cycling, hence one also expects He variations in addition to these anticorrelations. The actual amount of He variations depend on the nucleosynthetic site and the cluster chemical evolution (see, e.g., Decressin et al. 2007; D'Ercole et al. 2010, for two different scenarios to explain the observed abundance patterns).

Indeed, studies of the optical CMDs of MS stars³ have disclosed the presence of ranges of initial He in several GCs (see, e.g., Piotto et al. 2007; Milone et al. 2013; Nardiello et al. 2015, and references therein), including 47 Tuc (Milone et al. 2012). The synthetic HB modeling by di Criscienzo et al. (2010) and Gratton et al. (2013) also required a range of initial Y to reproduce the wedge-shaped HB in optical filters. On this issue, it may be worth recalling that in the past (see Dorman et al. 1989; Catelan & de Freitas Pacheco 1996) it was shown that at metallicities typical of 47 Tuc a wedge-shaped HB could be reproduced theoretically with a single but large initial Y , of the order of $Y \sim 0.30$. With our synthetic HB calculations we can obtain a shape roughly similar to the one observed for $Y = 0.34$ and a negligible Y range (and $\Delta M_{\text{RGB}} \sim 0.12M_{\odot}$). However, the resulting distance modulus is ~ 0.3 mag too large compared to constraints from the cluster eclipsing binaries (see below), and in addition cluster R-parameter studies (see, e.g., Cassisi et al. 2003; Salaris et al. 2004) exclude such high initial values of Y .

Finally, it is also important to mention that the observed CNONaMgAl abundance variations do not affect the stellar evo-

¹ Higher reddenings require a larger shift to the red of the HB models, hence a lower HB mass at a given colour, and an increased amount of RGB mass loss to match the observed HB location

² <http://www.oa-teramo.inaf.it/BASTI>

³ Light element anticorrelations do not affect the bolometric corrections for MS stars in optical CMDs, as shown by Sbordone et al. (2011)

Fig. 1. Comparison between the observed HB of 47 Tuc (triangles) with synthetic CMDs calculated with $\Delta M_{\text{RGB}}=0.23 M_{\odot}$ and $Y=0.256, 0.270$ and 0.286 (filled large circles) respectively, plus a simulation for $\Delta M_{\text{RGB}}=0.28 M_{\odot}$ and $Y=0.256$ (dots). Two HB tracks corresponding to $Y=0.256$, and masses $M=0.8$ and $0.9 M_{\odot}$ (corresponding to $\Delta M_{\text{RGB}}=0.12 M_{\odot}$ and $0.02 M_{\odot}$, respectively) are displayed as solid lines. All the tracks and synthetic CMDs are shifted by $E(B-V)=0.024$ and $(m-M)_V=13.40$ (see text for details).

lution tracks and isochrones as long as the CNO sum is unchanged (see, e.g., Pietrinferni et al. 2009; Cassisi et al. 2013) as generally true, within the spectroscopic measurements errors, with just a few exceptions. This justifies the use of standard α -enhanced models, with just varying initial He content.

To translate the RGB mass loss ΔM_{RGB} into HB masses we have to assume an age for the cluster, that provides (from the theoretical isochrones) the initial value of the mass of the stars evolving at the tip of the RGB (denoted as RGB progenitor mass). Age estimates by Salaris & Weiss (2002), Gratton et al. (2003), Dotter et al. (2010), VandenBerg et al. (2013) from CMD analyses provide a range between $t \sim 10.5$ and $t \sim 12.5$ Gyr, and we assumed for this simulation $t=11.5$ Gyr, that corresponds to a RGB progenitor mass equal to $0.92 M_{\odot}$. Our assumed age is also consistent with the estimated value $11.25 \pm 0.21 (\text{random}) \pm 0.85 (\text{systematic})$ Gyr by Thompson et al. (2010), based on theoretical mass-radius relations applied to the cluster eclipsing binary V69.

Figure 1 displays a first test that shows clearly the need for a substantial mass loss and a range of initial Y values to match the location and morphology of the cluster HB. The three narrow synthetic sequences in the figure (filled circles) that overlap with the observed CMD have been calculated for $Y=0.256$ (the *normal* initial He for the chosen initial metallicity according to the $\Delta Y/\Delta Z \sim 1.4$ ratio employed in the BaSTI calculations, and a cosmological $Y=0.245$), $0.270, 0.286$ respectively, $\Delta M_{\text{RGB}}=0.23$ and a negligible Gaussian spread $\sigma(\Delta M_{\text{RGB}})=0.001$. The synthetic sequences have been shifted in colour by applying the reference reddening $E(B-V)=0.024$, and in magnitude by adding

Fig. 2. Our baseline synthetic model for 47 Tuc HB (filled circles) compared to the observed HB (open triangles). The number of observed and synthetic stars within the box enclosing the observed HB is the same (see text for details).

an apparent distance modulus $(m-M)_V = 13.40$. This distance modulus is consistent with the estimates $(m-M)_V = 13.35 \pm 0.08$ (Thompson et al. 2010) and $(m-M)_V = 13.40 \pm 0.07$ (Kaluzny et al. 2007) from two eclipsing binaries in the cluster, and has been chosen to match the bottom-right end of the observed HB with models calculated with the normal initial He.

The increase of initial He abundance at fixed mass loss moves the synthetic stars towards bluer colours and brighter magnitudes. This progressive shift in colours and magnitudes plus the increased extension of the blue loops in the synthetic populations, reproduce well the wedge-shaped observed HB. For the reference age and metal composition, $\Delta M_{\text{RGB}}=0.23 M_{\odot}$ produces HB masses equal to $0.69, 0.66$ and $0.63 M_{\odot}$ for $Y=0.256, 0.270$ and 0.286 , respectively (see also a similar discussion in Gratton et al. 2013). On the other hand, synthetic stars with $Y=0.256$ and increased $\Delta M_{\text{RGB}}=0.28 M_{\odot}$ (dots) are displaced towards bluer colours but fainter magnitudes, confirming that the morphology of the cluster HB is driven by a range of Y rather than ΔM_{RGB} .

We have displayed also HB tracks for $Y=0.256$ and masses equal to 0.8 and $0.9 M_{\odot}$ (in order of increasing colour and decreasing magnitude), that correspond to $\Delta M_{\text{RGB}}=0.12 M_{\odot}$ and $0.02 M_{\odot}$, respectively. These tracks are beyond the red edge of the observed HB, and no variation of the adopted distance modulus can enforce an overlap with the data.

A full synthetic HB compared to the observed one is shown in Fig. 2. For this complete simulation we had to assume a statistical distribution for the initial He abundances, that for simplicity we considered to be uniform. The range of Y values spans the interval $0.256-0.286$ ($Y_{\text{min}}=0.256$ and $\Delta Y=0.03$), and $\Delta M_{\text{RGB}}=0.23 M_{\odot}$ like in Fig. 1, with a very small Gaussian spread of $0.005 M_{\odot}$. Photometric errors have been assumed to be Gaussian, with a mean value equal to 0.002 mag in both B and V magnitudes, as obtained from the photometric data. We restrict

Fig. 3. Comparisons of synthetic (solid line) and observed (filled circles) star counts with Poisson error bars in V -magnitude (top panel – bin size equal to 0.04 mag) and $(B - V)$ colour (bottom panel – bin size equal to 0.02 mag) bins, obtained from the data in Fig. 2 (see text for details).

our comparison to the objects within the box highlighted in the CMD (the precise choice of the boundaries of the box is not crucial). The simulation contains a much larger number of stars than observed, to minimize the Poisson error on the synthetic star counts, but here for the sake of clarity we show a subset of synthetic objects that matches the number of observed stars. We considered the match to be satisfactory when the observed mean magnitude ($\langle V \rangle_{\text{HB}} = 14.07$) and colour ($\langle (B - V) \rangle_{\text{HB}} = 0.80$), plus the associated 1σ dispersions (0.04 mag in both cases) are reproduced within less than 0.005 mag, and the overall shape of the observed star counts as a function of both $(B - V)$ and V is well reproduced. For the assumed reddening $E(B - V) = 0.024$, the mean $(B - V)$ colour is matched, and a distance modulus $(m - M)_V = 13.40$ allows to match also the observed mean V magnitude.

Figure 3 displays the resulting histograms of observed and synthetic star counts as a function of V and $(B - V)$ (star counts from the synthetic CMD are rescaled to match the observed total number of HB stars). The agreement looks very good even with these simple assumptions about mass loss and He distribution.

Figure 4 displays mass and Y distributions as a function of the colour of the synthetic stars displayed in Fig. 2. There is an obvious correlation with $(B - V)$ for both mass and Y , as expected from the constant ΔM_{RGB} (irrespective of Y) and very small $\sigma(\Delta M_{\text{RGB}})$ assumed in the simulation, that is blurred by the blue loops of the HB tracks (see Fig. 1). This is clear from the top panel, that shows how stars with a fixed mass are distributed over a large range of colours. Redder stars on the ZAHB are on average more massive and less He-enriched than bluer objects; the typical mass for the stars with normal $Y = 0.256$ is $\sim 0.69 M_{\odot}$, and decreases to $\sim 0.63 M_{\odot}$ for $Y = 0.286$. The average mass along the synthetic HB is equal to $0.66 M_{\odot}$, with a 1σ dispersion of $0.017 M_{\odot}$. The exact values of these two quantities depend on the

Fig. 4. Distribution of stellar mass (top panel) and initial Y values (bottom panel) as a function of the colour $(B - V)$, for the stars in the synthetic CMD displayed in Fig. 2.

assumed distribution of initial Y , but obviously the mean mass cannot be outside the range 0.63–0.69 M_{\odot} . A general trend of increasing Y with decreasing colour is also fully consistent with the observed trend of increasing Na towards bluer colours along the cluster HB (see Gratton et al. 2013).

We could have tried to enforce *a priori* the constraint of perfect statistical agreement between the theoretical and observed star counts. However, a perfect fit rests on the precise knowledge of the statistical distribution of ΔM_{RGB} and the initial Y among the cluster stars. Due to the current lack of firm theoretical and empirical guidance, this distribution may be extremely complicated and/or discontinuous. The constraints imposed on the matching synthetic HB are however sufficient to put strong constraints on ΔM_{RGB} –the main parameter discussed in this work– and the range of initial Y , which determine the region of the CMD covered by the observed HB.

In fact, just the observed shape of the HB allows a good determination of both ΔM_{RGB} and the Y range, when $E(B - V)$, age and initial chemical composition are fixed, as can already be inferred from Fig. 1. More in detail, Fig. 5 shows how changing these two parameters affects the shape and location of the synthetic HB. Variations of ΔM_{RGB} around the reference value –keeping the reference Y distribution fixed– move the location of the synthetic HB along the direction from the top-right corner of the CMD to the bottom-left one. At the same time the HB gets compressed when ΔM_{RGB} is reduced (shorter loops in the CMD of the HB tracks of larger mass) and stretched when ΔM_{RGB} is increased. No change of the cluster distance modulus can bring into agreement any of these two synthetic CMDs with the observed HB. Variations of ΔY –keeping the reference ΔM_{RGB} unchanged– stretch or compress the synthetic HB along the direction from the top-left corner of the CMD to the bottom-right one. Also in this case, variations of the cluster distance modulus do not compensate for the change of Y distribution.

Fig. 5. As Fig. 2, but for the labelled values of ΔM_{RGB} and ΔY (see text for details)

A decrease of ΔY to 0.025 and variations of ΔM_{RGB} within less than $0.01 M_{\odot}$ do still allow a satisfactory fit to the observed HB, according to the criteria described above, but larger variations are clearly ruled out because the resulting synthetic HB would clearly have a different shape than observed. Values of ΔM_{RGB} below $0.20 M_{\odot}$ are totally incompatible with the observed HB morphology and location in the CMD.

We have also experimented with a mass loss linearly dependent on the initial Y distribution. Considering $\Delta M_{\text{RGB}} = 0.23 M_{\odot}$ for the population with Y_{min} , a synthetic HB with $\Delta Y = 0.03$ and ΔM_{RGB} increasing at most as $0.5 \times \Delta Y$ provides a fit to the observations of comparable quality as the baseline simulation. This implies ΔM_{RGB} higher by just $0.015 M_{\odot}$ for the most He-rich component. Experiments with ΔM_{RGB} decreasing with Y show that at most ΔM_{RGB} can decrease as $0.15 \times \Delta Y$, implying a negligible decrease of the RGB mass loss as a function of Y .

As an additional test we have calculated a synthetic HB by considering the reference $\Delta M_{\text{RGB}} = 0.230 \pm 0.005$ (Gaussian spread) for all Y , but with a different distribution of initial He abundances. We have considered in this case 70% of the stars with a Gaussian distribution of initial Y characterized by mean value $\langle Y \rangle = 0.275$ and spread $\sigma(Y) = 0.007$, and the remaining 30% with a very narrow Gaussian distribution with $\langle Y \rangle = 0.258$ and spread $\sigma(Y) = 0.0008$. This choice stems from the results by Milone et al. (2012), who found a bimodal MS for this cluster, corresponding to ~ 0.02 difference in initial Y . The adopted distribution in our simulations has a difference of ~ 0.02 between the mean values of the two Gaussians, and a total range $\Delta Y = 0.03$, that is needed to cover completely the $V - (B - V)$ region occupied by observed HB. The 70/30 ratio comes again from Milone et al. (2012) analysis of the number ratio between the two populations of different initial He as a function of the distance from the cluster centre. For the same distance modulus of our reference simulation, mean V and mean $(B - V)$ of the observed HB are again matched within 0.01 mag, although star

counts as a function of colour and magnitude are slightly less well reproduced.

The main point of this simulation is that a change of the initial Y distribution of the HB stars does not affect the ΔM_{RGB} required to match the CMD location of the observed HB.

3. Analysis of the uncertainties

In the previous section we have found that for the adopted reference $[\text{Fe}/\text{H}] = -0.7$, $[\alpha/\text{Fe}] = 0.4$, $E(B - V) = 0.024$, $t = 11.5$ Gyr, our synthetic HB simulations require that RGB stars lose $\Delta M_{\text{RGB}} = 0.23 M_{\odot}$ (and have a range of initial He abundances $\Delta Y = 0.03$) to match the observed location and morphology of the HB, corresponding to stellar masses in the range $0.63 - 0.69 M_{\odot}$. This value of ΔM_{RGB} (and ΔY) is broadly in line with previous results based on synthetic HB modeling (di Criscienzo et al. 2010; Gratton et al. 2013), but in total disagreement with the conclusions by Heyl et al. (2015a) about RGB mass loss, based on cluster dynamics. Heyl et al. (2015a) results specifically exclude HB masses of the order of $0.65 M_{\odot}$. In the following we will discuss quantitatively how our reference estimate of ΔM_{RGB} may be affected by a series of observational and theoretical uncertainties.

3.1. Cluster reddening, age and chemical composition

The first obvious source of systematics is related to the range of reddening, chemical composition and age estimates found in the literature. We analyzed these effects by varying one parameter at a time. In all these cases the value of ΔY required to reproduce the observations is unchanged compared to the baseline case.

Increasing $E(B - V)$ (our baseline simulation has employed the lowest estimate of the cluster reddening) tends to increase ΔM_{RGB} . For example, assuming the widely employed value $E(B - V) = 0.04$, we obtain $\Delta M_{\text{RGB}} = 0.24 M_{\odot}$, whilst for the upper limit $E(B - V) = 0.055$ we obtain $\Delta M_{\text{RGB}} = 0.26 M_{\odot}$, e.g. we need lower masses to match the observed HB. As already mentioned, Marino et al. (2016) determined star-to-star variations around the mean reddening by at most -0.007 mag and $+0.009$ mag, respectively, with mean variations smaller than these extreme values. This amount of differential reddening will hardly affect the value of ΔM_{RGB} , as detailed below.

Let's assume –to maximize this effect– that the stars at the red edge of the observed HB have all a reddening 0.007 mag lower than the mean value. To compare with theory, their colours should then be increased by 0.007 mag (and their V magnitudes increased by ~ 0.02 mag) to reduce the observed HB to a single value of $E(B - V)$, causing a decrease of ΔM_{RGB} by just $\sim 0.01 M_{\odot}$ in this extreme case. At the same time, assuming all stars along the blue edge of the wedge have a reddening 0.009 mag higher than the mean value, their colours should be decreased by the same amount and their V magnitudes also decreased by ~ 0.03 mag. This would require a negligible increase of ΔY , and ΔM_{RGB} increasing with Y as $0.6 \times \Delta Y$.

As for the age, a variation by ± 1 Gyr around the reference value causes a change of the RGB progenitor mass by about ± 0.02 (lower mass for increasing age). The best fit synthetic HB requires the same HB mass distribution as the baseline case, but ΔM_{RGB} varies by about ± 0.02 (decreased when the age increases) because of the change of the RGB progenitor mass.

We considered then the range of $[\text{Fe}/\text{H}]$ estimates $[\text{Fe}/\text{H}] = -0.7 \pm 0.1$. Increasing $[\text{Fe}/\text{H}]$ of the models tends to increase ΔM_{RGB} for two reasons. First, because at fixed age

the RGB progenitor mass increases by $\sim 0.01 M_{\odot}$ for a 0.1 dex increase of $[\text{Fe}/\text{H}]$ (due to longer evolutionary timescales at fixed mass) and second, HB tracks are redder, so that for a fixed reddening lower HB masses are required to match the observed HB location. If we consider $[\text{Fe}/\text{H}] = -0.6$ – the approximate upper limit of the spectroscopic determinations – keeping everything else unchanged, the best fit synthetic HB model has $\Delta Y = 0.03$, $\Delta M_{\text{RGB}} = 0.28 M_{\odot}$ and $(m - M)_V = 13.35$. When employing the approximate lower limit $[\text{Fe}/\text{H}] = -0.8$, after interpolation in metallicity amongst the grid of BaSTI models we obtain a best match for $\Delta Y = 0.03$, $\Delta M_{\text{RGB}} = 0.18 M_{\odot}$ and $(m - M)_V = 13.47$. In these cases the mean mass of the synthetic HB stars varies by $\sim 0.03 M_{\odot}$ (increases when $[\text{Fe}/\text{H}]$ decreases) around the mean value of the baseline simulation.

If we decrease $[\alpha/\text{Fe}]$ from 0.4 dex to 0.3 dex, keeping $[\text{Fe}/\text{H}]$ and all other parameters unchanged, after interpolations amongst our models we found that ΔM_{RGB} decreases by just 0.01–0.02 M_{\odot} (the HB mean mass changes by less than this, because of the corresponding variation of the RGB progenitor mass, as for the case of changing $[\text{Fe}/\text{H}]$) and $(m - M)_V$ increases by ~ 0.02 mag compared to our baseline simulation.

To summarize, variations of the cluster chemical composition, age and reddening do not change much ΔM_{RGB} , and especially the typical HB stellar mass, compared to the results of the baseline simulation. In the following we discuss whether considering a number of uncertainties in the theoretical models can help solving or at least minimizing the disagreement with inferences from cluster dynamics.

3.2. Bolometric corrections and colour transformations

To compare the output of stellar evolution calculations (L and T_{eff}) with observed CMDs the use of bolometric corrections (BCs) and colour- T_{eff} relationships is essential. One way to proceed is to calculate grids of model atmospheres and synthetic spectra, that are integrated under the appropriate filter transmission functions to get fluxes in a given passband, which are then suitably normalized to calculate BCs and colours (see, e.g. Girardi et al. 2002; Casagrande & Vandenberg 2014, and references therein). Our adopted set of models employs theoretical BCs and colours calculated from ATLAS9 model atmospheres and spectra (see Pietrinferni et al. 2004, 2006, for details). We have tested also the results from PHOENIX model atmosphere calculations employed by the Dartmouth stellar model library (Dotter et al. 2008), and found that at the relevant metallicities the HB tracks become systematically redder than with ATLAS9 results. This shift would cause lower HB masses from synthetic HB modeling, hence higher ΔM_{RGB} at fixed age, reddening and chemical composition.

An alternative approach is to employ empirical or semiempirical results, when available. Worthey & Lee (2011) have recently presented essentially empirical BCs and colour- T_{eff} relationships in various broadband filters based on a collection of photometry for stars with known $[\text{Fe}/\text{H}]$.

Figure 6 displays representative $0.7 M_{\odot}$ and $0.8 M_{\odot}$ HB tracks with our adopted reference chemical composition and $Y = 0.256$, shifted by $E(B - V) = 0.024$ and $(m - M)_V = 13.40$ as in our baseline simulation. The same tracks are displayed after applying BCs and colour transformations from Worthey & Lee (2011), using the routine provided by the authors. This routine gives also the errors associated to the computed BCs and colours, and we display in the figure the brightest/bluest and faintest/redest limits of the area covered by these error bars, that are of about 0.05 mag in BC_V and ~ 0.02 mag in $(B - V)$.

Fig. 6. HB evolutionary tracks for 0.7 (top panel) and $0.8 M_{\odot}$ (bottom panel), $[\text{Fe}/\text{H}] = -0.7$, $[\alpha/\text{Fe}] = 0.4$, $Y = 0.256$ HB models shifted by $E(B - V) = 0.024$ and $(m - M)_V = 13.40$, compared to the cluster HB. The dotted lines display the BaSTI tracks with the adopted BaSTI BCs and colour transformations, while the solid lines show the same tracks but employing the empirical Worthey & Lee (2011) BCs and colours. Dashed lines in each panel display the brightest/bluest and faintest/redest extremes of the error range associated to Worthey & Lee (2011) transformations.

It is clear from the figure that these transformations make the tracks redder (and very slightly fainter) than the reference BaSTI models, but within the empirical error bars ATLAS9 transformations (adopted in the BaSTI library) are consistent with Worthey & Lee (2011) results. There isn't much room for a substantial increase of the typical HB mass when considering these empirical results. Masses above $\sim 0.7 M_{\odot}$ along the HB are still clearly excluded.

To get more quantitative results we have calculated synthetic HB models for the reference chemical composition and reddening by using Worthey & Lee (2011) results. We found a best match to the observed HB for $\Delta M_{\text{RGB}} = 0.24 M_{\odot}$ – very close to the result of our baseline simulation of Sect. 2 – $(m - M)_V = 13.38$, all other parameters being the same as in our reference simulation of Sect. 2. By employing the bluest colours allowed by the error bars on Worthey & Lee (2011) results – to minimize the value of ΔM_{RGB} and the HB masses needed by the HB simulations – we obtained $\Delta M_{\text{RGB}} = 0.22 M_{\odot}$, and a mean HB mass equal to $\sim 0.67 M_{\odot}$. Considering also the errors on BC_V would simply shift the synthetic HB vertically by ± 0.05 mag, implying an adjustment of the derived $(m - M)_V$ by the same amount, that is still within the errors of the eclipsing binary distance estimates.

3.3. Model calculation, input physics

Before the start of the HB phase GC stars go through the violent core helium flash at the tip of the RGB. Until recently only

few calculations have been able to calculate the evolution of stellar models through this event, and traditionally HB models (including the BaSTI models employed in our analysis) have been computed by starting new sequences on the HB, where the initial structure is taken from that at the tip of the RGB. The underlying assumption of such methods (consistent with the results of stellar evolution calculations that follow the helium flash evolution) is that during the helium flash the internal (and surface) chemical structure is not altered significantly, apart from a small percentage of C produced in the He-core during the flash.

The technique employed in BaSTI models (denoted as Method 2 in the work by Serenelli & Weiss 2005) envisages that a model at the beginning of the core helium flash is employed as the starting model for the ZAHB calculation. The core mass and chemical profile of the initial pre-flash configuration are kept unchanged. The total mass of the ZAHB model is either preserved or reduced (to produce a set of ZAHB models of varying total mass) by rescaling the envelope mass. The new model on the ZAHB is then converged and *relaxed* for a certain amount of time (typically 1 Myr) to attain CNO equilibrium in the H-burning shell (see, e.g., Cassisi & Salaris 2013) before being identified as the new ZAHB model. A 5% mass fraction of carbon is added to the He-core composition, guided by requirement that the energy needed for the expansion of the degenerate helium core must come from helium burning (Iben & Rood 1970).

VandenBerg et al. (2000) and with more details Piersanti et al. (2004) and Serenelli & Weiss (2005), have compared the ZAHB location and HB evolution of models whose RGB progenitor evolution was properly followed through the He-flash, with results with our method described before. Especially for red HB models, like the case of 47 Tuc HB, differences in T_{eff} , L and time evolution turned out to be negligible.

As additional potential sources of uncertainty in the determination of ΔM_{RGB} employing synthetic HB modeling, we considered the effect of uncertainties in the current input physics adopted in stellar model calculations. We considered first the effect on the He-core mass at the He flash and how this affects the HB tracks, and then the effect on the HB evolution at fixed core mass.

Since the calculation of the BaSTI model database, two relevant physics inputs, i.e. the $^{14}\text{N} + \text{p}$ reaction rate and the electron conduction opacities, have been subject to revised and improved determinations. The recent Cassisi et al. (2007) calculations of electron conduction opacities—larger than the Potekhin (1999) results used in the BaSTI calculations—cause a variation of the He-core mass at the He flash (ΔM_{He_c}) by $-0.006 M_{\odot}$, compared to our adopted HB models. On the other hand, the new Formicola et al. (2004) tabulations of the $^{14}\text{N} + \text{p}$ reaction rate—lower by a factor ~ 2 than the Angulo et al. (1999) rate used in our adopted models—induce an increase $\Delta M_{\text{He}_c} \sim 0.0025 M_{\odot}$ compared to the BaSTI calculations. The combined effect is a minor change $\Delta M_{\text{He}_c} \sim -0.0035 M_{\odot}$ compared to the BaSTI models.

In addition, Valle et al. (2013) have determined ΔM_{He_c} due to realistic uncertainties in the Formicola et al. (2004) $^{14}\text{N} + \text{p}$ reaction rate ($\pm 10\%$), the Cassisi et al. (2007) electron conduction opacities ($\pm 5\%$), plus the $^1\text{H} + \text{p}$ ($\pm 3\%$) and 3α ($\pm 20\%$) reaction rates, neutrino emission rates ($\pm 4\%$) and the radiative opacities ($\pm 15\%$) used in the BaSTI models. If we simply add together the effect of these uncertainties plus the systematic effect of including fully efficient atomic diffusion in the pre-HB

Fig. 7. As Fig. 6 but displaying for the $0.8 M_{\odot}$ standard BaSTI track (solid line in both panels), the effect of changing the He-core mass at the He-flash by $\pm 0.02 M_{\odot}$ (dashed lines in the left panel), the amount of He dredged to the surface by the first dredge up by $\delta Y_{\text{FDU}} = \pm 0.02$ (dash-dotted lines in the left panel), the $^{12}\text{C} + \alpha$ reaction rate (doubled and halved, respectively – dotted lines in the left panel), the mixing length α_{MLT} by -0.15 (dashed line in the right panel), the Rosseland mean opacities by $\pm 5\%$ (dotted lines in the right panel) and the $^{14}\text{N} + \text{p}$ reaction rate from the Angulo et al. (1999) to the Formicola et al. (2004) tabulations (dash-dotted line in the right panel).

calculations⁴—that increases M_{He_c} by $\sim 0.004 M_{\odot}$, see Table 7.2 in Cassisi & Salaris (2013)—and the $\Delta M_{\text{He}_c} \sim -0.0035 M_{\odot}$ discussed before, we obtain a (conservative) variation $\Delta M_{\text{He}_c} \sim \pm 0.01 M_{\odot}$ around the value obtained from the BaSTI calculations.

The left-hand panel of Fig. 7 displays the effect of $\Delta M_{\text{He}_c} = \pm 0.02 M_{\odot}$ on a $0.8 M_{\odot}$ HB track for the reference chemical composition $Y=0.256$, $[\text{Fe}/\text{H}]=-0.7$ and $[\alpha/\text{Fe}]=0.4$. To calculate this track we varied the He-core mass by $\pm 0.02 M_{\odot}$ around the value provided by the BaSTI models ($M_{\text{He}_c} = 0.48 M_{\odot}$) and recalculated the HB evolution, everything else being kept fixed. This variation is even larger than the estimates discussed before and takes into account two additional factors. First, a possible extra increase of M_{He_c} due to the effect of rotation, as originally discussed by Castellani & Tornambe (1981) and Lee et al. (1994) in the context of synthetic HB modeling; second, a potential additional decrease by $\sim 0.008 M_{\odot}$ due to the use of weak screening in the He-core during the whole RGB evolution, instead of the transition to intermediate and strong screening when appropriate, following the treatment by Graboske et al. (1973) as implemented in the BaSTI calculations.

It is clear from the figure that the expected shift in magnitude of the tracks (higher M_{He_c} corresponds to higher luminosity) is not accompanied by any major shift in colour. The ZAHB location is only very slightly redder for the lower core mass model, and bluer for the higher core mass one, and the extension of the

⁴ The BaSTI models neglect atomic diffusion

loops in the CMD is only slightly altered. It may seem puzzling that such a large variation of M_{He_c} hardly affects the tracks. In fact HB tracks of a given total mass are generally sensitive to small variations of the He-core mass at the flash, because of the changed efficiency of the H-burning shell, due to the corresponding variation of the mass of the H-rich envelope. However, at this metallicity and for massive HB models, the efficiency of the burning shell is only weakly altered even by a $\pm 0.02 M_\odot$ change of M_{He_c} , because this corresponds to just a small percentage variation of the mass thickness of the envelope.

The same figure shows also the effect of arbitrarily altering the efficiency of the first dredge-up on the same $0.8 M_\odot$ HB track, keeping everything else unchanged. Our adopted BaSTI models predict an increase of the surface He mass fraction by 0.02 for the cluster RGB stars. This increased He abundance in the envelope impacts the efficiency of the H-burning shell during the HB phase. We tested a variation of the dredged up He mass fraction $\delta Y_{FDU} = \pm 0.02$, by recalculating HB models with this new envelope chemical abundance; the resulting tracks are simply shifted in luminosity (higher for increasing He abundance) but their colour location is unchanged.

We have then considered the HB evolution of the same $0.8 M_\odot$ HB track keeping M_{He_c} fixed, and varying once at a time the most relevant inputs like the radiative opacities by $\pm 5\%$, the $^{14}\text{N} + \text{p}$ reaction rate from the Angulo et al. (1999) tabulations used in our adopted BaSTI models to the most updated Formicola et al. (2004) tabulations, the superadiabatic convection mixing length parameter by $\delta \alpha_{MLT} = -0.15$ compared to the solar calibrated value ($\alpha_{ml,\odot} = 2.01$) of the BaSTI calculations (see right-hand panel of Fig. 7) and the $^{12}\text{C} + \alpha$ reaction rate (doubled and halved, respectively, as shown in the left-hand panel of Fig. 7).

As already mentioned, the Formicola et al. (2004) $^{14}\text{N} + \text{p}$ rate is about a factor of two lower than the Angulo et al. (1999) result, i.e., a variation much larger than the error associated to this improved rate. Regarding the variation $\delta \alpha_{MLT} = -0.15$ with respect to the solar calibrated value, this is what the fitting formulas by Magic et al. (2015) –based on the results of a large grid of 3D radiation hydrodynamics simulations– predict for the surface gravity-effective temperature regime of the $0.8 M_\odot$ HB track, and a metallicity $[\text{Fe}/\text{H}] = -0.5$, close to the value adopted in our calculations. We consider this adopted $\delta \alpha_{MLT}$ as a qualitative estimate of the uncertainty on the efficiency of superadiabatic convection in the envelope of red HB stars. Regardless of the precise estimate of $\delta \alpha_{MLT}$, Magic et al. (2015) simulations (a similar behaviour is found also in an analogous 3D hydro-calibration by Trampedach et al. 2014, at solar metallicity) predict that α_{MLT} should decrease towards higher effective temperature and/or lower surface gravity compared to the solar values. As for the $^{12}\text{C} + \alpha$ reaction rate, we consider both an increase and a decrease by a factor of two with respect to the reference rate adopted in the BaSTI calculations (Kunz et al. 2001), along the lines of the analysis by Gai (2013) regarding the current uncertainties on this reaction rate.

It is clear from the figure that the variation of the opacity (higher opacity corresponds to lower luminosities) and $^{14}\text{N} + \text{p}$ reaction rate alter essentially just the brightness of the model, not the colour, as for the case of varying M_{He_c} and Y_{FDU} . The variation of the $^{12}\text{C} + \alpha$ reaction rate alters only very marginally the extension of the blueward loop in the CMD (more extended loop for an increase of the reaction rate). The variation of the mixing length obviously affects the model colours, but the decrease of α_{MLT} predicted by the hydro-simulations makes the model red-

der, thus decreasing the mass of the HB models –hence increasing the RGB mass loss– needed to match the observed HB.⁵

Finally, we considered the effect of the treatment of core mixing during the HB phase. As well known and discussed recently again by, e.g., Gabriel et al. (2014) and Constantino et al. (2015), the treatment of convective boundaries during core helium burning is still an open question in stellar evolution calculations, and is handled in different ways by different stellar evolution codes. Recent advances in asteroseismic observations and techniques (Bossini et al. 2015; Constantino et al. 2015) are starting to add very direct observational constraints to the core mixing process during the central He-burning phase, that coupled to theoretical inferences and indications from star counts in Galactic globular clusters (see, e.g., Caputo et al. 1989; Gabriel et al. 2014; Cassisi et al. 2003, and references therein), make a strong case for the core mixed region to be extended beyond the Schwarzschild border. Questions exist however about the treatment of this extended mixing. The details do not affect the ZAHB location of the models, but can potentially modify the extension of the loops in the CMD and have some relevance for the determination of the mass range of the cluster HB population.

Our adopted BaSTI HB models include semiconvection in the core (see Castellani et al. 1971b,a, 1985), with the suppression of the breathing pulses in the last phases of central He-burning with the technique by Caputo et al. (1989), following the observational constraints discussed by Cassisi et al. (2003). Constantino et al. (2016) have calculated and compared HB models with different treatment of core mixing beyond the Schwarzschild border, and in their Fig. 7 they compare HB tracks for a $0.83 M_\odot$, $[\text{Fe}/\text{H}] = -1$, initial $Y = 0.245$, not very different from the case discussed in this section. Tracks with two different types of overshooting (one of them, the *maximal overshoot* case, reproduces best the asteroseismic constraints, as discussed by Constantino et al. 2015) and with semiconvection are almost indistinguishable.

As a conclusion, none of the large list of uncertainties discussed in this section, appears to be able to shift onto the observed HB substantially more massive HB tracks, compared to the baseline simulation.

4. Discussion and conclusions

In the previous sections we have investigated in detail the constraints posed by the CMD of HB stars on the RGB mass loss in the Galactic globular cluster 47 Tuc, using synthetic HB modeling. We confirm the results by di Criscienzo et al. (2010) and Gratton et al. (2013) about the need for a range of initial He abundances (we find $\Delta Y = 0.03$) to reproduce properly the observed HB morphology. This abundance range is broadly consistent with the range inferred from the analysis of the cluster MS. For the values of age (11.5 Gyr), metal content ($[\text{Fe}/\text{H}] = -0.7$ and $[\alpha/\text{Fe}] = 0.4$) and reddening ($E(B - V) = 0.024$) adopted in our baseline simulation, a total mass loss of individual RGB stars $\Delta M_{\text{RGB}} = 0.23 M_\odot$ (with a very small dispersion) independent of Y is required to reproduce the observed HB location and morphology. This value for ΔM_{RGB} is consistent with the estimates by Origlia et al. (2007) from mid-IR photometry and the results by di Criscienzo et al. (2010) and Gratton et al. (2013) from sim-

⁵ Somewhat surprisingly also the V-band magnitude of the model with changed mixing length is affected, although this is due exclusively to the bolometric corrections, that change because of the decrease of the model effective temperature

ilar synthetic HB modeling. The mean mass of the synthetic HB stars in this simulation is equal to $0.66M_{\odot}$.

To assess the robustness of this estimate of ΔM_{RGB} and the HB masses, we have then considered several possible sources of uncertainty that could affect the HB modeling, stemming from uncertainties in both cluster parameters and model calculations. Uncertainties in the cluster reddening, age and $[\text{Fe}/\text{H}]$ have the largest effect on the derived ΔM_{RGB} . Considering an age of 12.5 Gyr (approximately the upper limit consistent with current estimates), $[\text{Fe}/\text{H}] = -0.8$ (the lower limit of spectroscopic estimates) and the lowest reddening estimate $E(B - V) = 0.024$ could potentially lead to $\Delta M_{\text{RGB}} < 0.20M_{\odot}$. Younger ages, higher metallicities and reddenings, within the range of current estimates, can however increase the estimated ΔM_{RGB} up to $\sim 0.30M_{\odot}$. A fraction of this range of ΔM_{RGB} values is due to the variation of the RGB progenitor mass with age and initial chemical composition, so that the actual variation of the typical HB masses is smaller than the full range of ΔM_{RGB} .

There is however the additional constraint posed by the observed colour of the RGB that can be considered. As we show in the following, this will narrow the range of ΔM_{RGB} and HB masses allowed by the analysis of the cluster CMD. The upper panel of Fig. 8 shows the synthetic CMDs of our baseline simulation described in Sect. 2 ($[\text{Fe}/\text{H}] = -0.7$, $[\alpha/\text{Fe}] = 0.4$, $E(B - V) = 0.024$, age $t = 11.5$ Gyr, $\Delta Y = 0.03$, $\Delta M_{\text{RGB}} = 0.23M_{\odot}$, $(m - M)_V = 13.40$) together with the corresponding RGB isochrone (also from the BaSTI models, using the reference ATLAS9 transformations), compared to the cluster photometry, in the magnitude range around the HB. Obviously the theoretical RGB is too red compared to the data; given that $E(B - V) = 0.024$ is the lowest reddening estimate, there is no room for shifting to the blue the position of the theoretical RGB (that is virtually insensitive to age and initial Y for the relevant age and He-abundance ranges). This implies that our adopted models with $[\text{Fe}/\text{H}] = -0.7$ are inconsistent with the observations.

The lower panel of Fig. 8 displays the best match synthetic HB simulation when applying the Worthey & Lee (2011) transformations to our adopted BaSTI stellar models, keeping $[\text{Fe}/\text{H}] = -0.7$, $[\alpha/\text{Fe}] = 0.4$, $E(B - V) = 0.024$, $t = 11.5$ Gyr, as in the baseline simulation of the top panel. We derive in this case, as already discussed, $\Delta Y = 0.03$, $\Delta M_{\text{RGB}} = 0.24M_{\odot}$, $(m - M)_V = 13.38$. The position of the RGB is again largely inconsistent with observations, even allowing for the errors on the Worthey & Lee (2011) BCs and colour transformations, displayed in the figure.

Figure 9 shows an analogous comparison, but for $[\text{Fe}/\text{H}] = -0.8$ ($[\alpha/\text{Fe}] = 0.4$), $t = 11.5$ Gyr. In the top panel –the case with the ATLAS9 BCs and colours– the theoretical RGB matches the average colour of observed one for $E(B - V) = 0.035$, and the best match synthetic HB has $\Delta Y = 0.03$, $\Delta M_{\text{RGB}} = 0.19M_{\odot}$, $(m - M)_V = 13.46$. The average mass along the synthetic HB is in this case equal to $0.69M_{\odot}$, with a 1σ dispersion of $0.017M_{\odot}$, and a full range between $\sim 0.65M_{\odot}$ and $\sim 0.73M_{\odot}$.

The bottom panel displays the case with the Worthey & Lee (2011) transformations, for $[\text{Fe}/\text{H}] = -0.8$ ($[\alpha/\text{Fe}] = 0.4$), $t = 11.5$ Gyr, $E(B - V) = 0.035$. The only way to match the observed RGB is to consider the bluest colors allowed by the errors on these empirical transformations, whilst for the HB the reference BCs and colour transformations provided by Worthey & Lee (2011) allow a match with observations for $\Delta Y = 0.03$, $\Delta M_{\text{RGB}} = 0.19M_{\odot}$, $(m - M)_V = 13.44$, almost identical to the case with the ATLAS9 transformations.

One can speculate whether considering the bluest limit of Worthey & Lee (2011) colour transformations also for the HB models, might decrease ΔM_{RGB} , because the synthetic HB

Fig. 8. As Fig. 2 but including also the observed and theoretical RGB sequences. The top panel displays the $[\text{Fe}/\text{H}] = -0.7$ baseline simulation employing the BaSTI adopted BCs and colour transformations (ATLAS9). The bottom panel shows the result for the baseline simulation but employing the empirical Worthey & Lee (2011) BCs and colour transformations (solid line). The reddest and bluest limits of the RGB colours according to the errors on the Worthey & Lee (2011) transformations and BCs are displayed as dotted lines (see text for details).

should then made redder while keeping reddening, age and chemical composition fixed. However, an increase of the HB masses –hence a decrease of ΔM_{RGB} below $\sim 0.19M_{\odot}$ – would cause a shift to the red of the HB, but also a change of the HB morphology that is inconsistent with the observations, like the case discussed in the lower-left panel of Fig. 5. With increasing HB mass the loops in the CMD do shrink, and it is impossible to match at the same time the vertical and horizontal thickness of the observed HB by changing the Y distribution.

In summary, the additional constraint posed by the colour of the RGB narrows down the possible range of $[\text{Fe}/\text{H}]$, $E(B - V)$ and ΔM_{RGB} . A fit for the minimum estimate $E(B - V) = 0.024$ could be in principle achieved, at least with the ATLAS9 transformations, considering a slightly higher $[\text{Fe}/\text{H}]$, between ~ -0.8 and ~ -0.75 dex, but this would keep ΔM_{RGB} (and the evolving HB masses) roughly unchanged because of the compensating effects of increasing $[\text{Fe}/\text{H}]$ and decreasing reddening, discussed in the previous sections.

A firm estimate of the minimum RGB mass loss allowed by our modeling is therefore $\Delta M_{\text{RGB}} \sim 0.17M_{\odot}$ if we consider a cluster age of 12.5 Gyr, that is approximately the upper limit of current estimates. The maximum ΔM_{RGB} is equal to $\sim 0.21M_{\odot}$, for an age of 10.5 Gyr. The resulting mass distribution of the HB stars is in both cases between $0.65M_{\odot}$ and $0.73M_{\odot}$, the full range determined mainly by the range of initial Y abundances of the progenitors ($\Delta Y = 0.03$). The derived distance modulus is consistent with constraints from the observed cluster eclipsing binaries.

Fig. 9. As Fig. 8, but for simulations with $[\text{Fe}/\text{H}] = -0.8$ (see text for details).

We can also compare ΔM_{RGB} with the expected mass loss during the following AGB phase (ΔM_{AGB}). In the simulation that minimizes ΔM_{RGB} , the initial progenitor mass of the HB stars is equal to $\sim 0.89 M_{\odot}$ for the $Y=0.254$ population, and $\sim 0.84 M_{\odot}$ for the $Y=0.284$ population. Assuming that the final WD mass will be equal to $\sim 0.53 M_{\odot}$ (Kalirai et al. 2009) irrespective of the initial Y , the mass to be shed by the cluster stars during the AGB phase will range between $\Delta M_{\text{AGB}} \sim 0.19 M_{\odot}$ for the $Y=0.254$ population, and $\sim 0.14 M_{\odot}$ for the $Y=0.284$ population. The value of ΔM_{RGB} is therefore expected to be similar to the average ΔM_{AGB} , whose precise value depends on the distribution of initial Y . For a flat Y distribution the average ΔM_{AGB} is equal to ΔM_{RGB} .

On the whole our detailed analysis confirms the discrepancy between information coming from cluster dynamics and CMD modeling of the HB. The lower limit for ΔM_{RGB} allowed by the HB modeling is only slightly lower than the $0.20 M_{\odot}$ value excluded with high confidence by Heyl et al. (2015a) analysis. The predicted mass distribution of HB stars is between $\sim 0.65 M_{\odot}$ and $\sim 0.73 M_{\odot}$, with mean value –that depend on the exact Y distribution– not much higher than $0.65 M_{\odot}$, this latter excluded by Heyl et al. (2015a) analysis. On the other hand the RGB mass loss allowed by the HB modeling is consistent with $\Delta M_{\text{RGB}} \sim 0.23 \pm 0.07 M_{\odot}$ estimated from the detection of their circumstellar envelopes by means of mid-IR photometry (Origlia et al. 2007).

A comparison between the results from these two techniques applied to other clusters is required, to gain more insights about the origin of this apparently major disagreement between CMD and dynamical results.
